Abstract: Small bowel evisceration through the vagina is a rare surgical emergency that requires urgent surgical intervention because of the risk of developing acute small bowel ischemia. The clinical case is represented by an 81-year-old patient with vaginal intestinal evisceration, known in the past with 5 natural births, uterine cerclage in the last pregnancy, persistence of vaginal prolapse for 20 years. Gut evisceration was caused by the postmenopausal period, atrophic vagina caused by the enterocele susceptible to rupture from increased intra-abdominal pressure or trauma. From the pathogenic point of view, the lesion of an anatomical structure, as in the case reported by us of the posterior vaginal recess with the evisceration of the small intestine (ileum) in its evolution, initially achieves an inflammatory contact from the first stages. Objectives: to present the surgical emergency, the etiology, the possible complications and the method of choice for the treatment of the given pathology. Material and methods: were composed from the specialty literature, the case was elucidated by surgical intervention through a double approach: transabdominal and transvaginal. The multidisciplinary team was composed of general surgeons, gynecologist and anesthetist. Results: The results of the given case show the importance of rapid resolution of intestinal evisceration to avoid bowel ischemia and minimize the risk of subsequent recurrence. Conclusion: Early detection and surgical management of this rare surgical emergency is imperative to prevent small bowel ischemia that may require resection and the development of sepsis and systemic inflammatory response syndrome due to intestinal necrosis that may ultimately lead to death.

Keywords: vaginal prolapse, evisceration, cystocele.

Introduction:

Studies in the field have reported conclusive data, according to which vaginal evisceration can occur as a result of an injury, either trauma or following a uterine, vaginal surgical intervention, or it can even occur spontaneously as a result of increased intra-abdominal pressure, having as a contributing factor the effort during the act of defecation or cough [1]. Transvaginal gut evisceration was first described by Hypernaux in 1864 [2]. Currently, there are a little over 130 published cases [3].

Clinical case:

We present a clinical case of vaginal evisceration due to perforation of the posterior vaginal wall through the perineum. The diagnosis was confirmed by physical assessment followed by emergency surgery, which ultimately had a positive outcome. The 81-year-old patient is admitted to the clinic for a vaginal evisceration. The given complication assessed insidiously 3 days ago and had a progressive evolution. According to the anamnestic data, the patient has 5 natural births, and the last sexual act took place at the age of 60, (21 years ago). The patient presented herself as an emergency in the General Surgery Clinic of St. Spiridon Hospital, Iaşi by inter-hospital transfer from the territory, with accusations of vaginal evisceration with an onset 3 days ago (ABP: 110/70mmHg; Ps: 78b/min ). The patient was diagnosed 20 years ago with vaginal prolapse. Gynecological consultation: Erosion of the posterior vaginal wall, complicated with intestinal perforation and evisceration. Total vaginal prolapse. In the past, she underwent uterine cerclage during her last pregnancy. The preoperative diagnosis: Intestinal evisceration through perforation of the posterior vaginal wall. Vaginal erosion. Total vaginal prolapse.

Table 1: Laboratory examinations (preoperative and postoperative).

In the context of what has been reported, surgical intervention is performed, and the decision for an operation as early as possible was made by evaluating the condition of the eviscerated intestine, with the aim of avoiding intestinal resection, if the condition of the eviscerated intestine (ileum) allows it (Figure 1). The surgical intervention was performed by a multidisciplinary team composed of general surgeons, gynecologist and anesthesiologist, through a double approach: transabdominal and transvaginal. Intraoperatively, a careful review of the eviscerated small intestine (ileum) (Figure 2), the state of the vaginal wall, the place of evisceration, the nature of the vaginal perforation (Figure 3), and the viability of the eviscerated intestinal loop is initially practiced. The operation field was washed and the intestinal loop was repositioned in the peritoneal cavity through an anterior abdominal approach followed by plasty of the posterior recess of the vagina (Figure 3B).

and uterine promontofixation (Figure 4). A urinary catheter (Foley 18FR) was mounted in the urinary bladder.

Postoperatively, according to the antibiogram, the empiric antibiotherapy course as well as hydroelectrolytic, acid-base, metabolic rebalancing and antifungal treatment continued. The postoperative evolution is favorable with discharge at home on the 10th postoperative day with the following recommendations: Monitoring at the family doctor, obstetrics and gynecology dispensary, conservative treatment (local baths, anti-inflammatory).

Discussion:
Vaginal evisceration, although extremely uncommon, has been most commonly reported in postmenopausal women. Most had a history of hysterectomy, multiple vaginal operations (vaginal prolapse, enterocele, cystocele, rectocele) [4]. Less often after intercourse. In such cases: whether the walls of the postmenopausal vagina are thin, scarred and shortened, predisposing to spontaneous, post-traumatic rupture or an already atrophic postmenopausal vagina that is stretched by an advancing enterocele, as in our case, making it susceptible to rupture from increased intra-abdominal pressure or trauma [5]. As a result, the morphopathological changes induced by the evolution of the disease are expressed diffusely, depending on the clinical-evolutionary stage.

There are studies that have shown that most women who have been diagnosed with vaginal evisceration have had previous vaginal surgery. Kowalski (1996) reporting a 67% incidence of vaginal surgery in postmenopausal patients studied. Analyzing the literature, we found that at least 54% of all women experiencing vaginal eviscerations had previous vaginal surgery, ranging from 1 day to 15 years after the last procedure [6]. From the pathogenic point of view, the lesion of an anatomical structure, as in the case reported by us of the posterior vaginal recess with the evisceration of the small intestine (ileum) in its evolution, initially and at stages achieves an inflammatory contact. Thus, angiogenesis at the contact site, in the case of the vaginal wall, stimulated by inflammatory hypoxia by means of peptides belonging to endothelial growth vessels (VEGF) or inflammatory mediators (interleukins, cytokines, TNF), in turn contribute to structural anatomical changes at perforation. So, fistulization occurs following the perforation of the vaginal wall [7]. The particular evolution of the disease and hence the delay in diagnosis and appropriate therapy associate serious complications, the least common – perforation of the vaginal wall with intestinal evisceration. The late diagnosis of the anatomical-functional condition of the vaginal wall that complicates vaginal evisceration can lead to the development of an aggressive endotoxicosis and the initiation of plurivisceral
Evisceration of small bowel through the vagina has a mortality rate of 6% [8]. A careful medical evaluation and well-argued management of such emergencies taken into account allow us to initiate maneuvers to stabilize the patient's general state of hydroelectrolytic, acid-base, metabolic rebalancing, the mounting of wet saline sponges on the eviscerated intestine, under early antibiotic therapy, imaging evaluation by ultrasound, radiography to exclude foreign bodies, other comorbidities and to intervene promptly surgically. The emergency surgical technique will be through both the abdominal and vaginal approach, establishing the condition of the loop of the eviscerated intestine, the vascularization, in advanced cases practicing the resection of any segment of compromised intestine, as well as necrotic vaginal tissue, the careful washing of the contaminated areas and the restoration of the vaginal wall [5,8,9,10].

Conclusions:
As a practical conclusion, we would like to emphasize that in the presence of vaginal prolapse in postmenopausal women, even if the evolutionary semiology of the given condition is non-specific, it must definitely lead to the clinical-paraclinical exploration carried out by the gynecologist, especially in inflammatory processes, infectious diseases added to the background pathology or other complications. The presented case is evocative due to the presence of associated complications, erosive changes, perforation, gut evisceration, the seriousness of which is much more important.
